INTRODUCTION

Definition of the normal anatomy of the human embryo is essential to assess embryonic development and growth as well as to identify and diagnose congenital anomalies in early pregnancy. A major limitation to define, noninvasively, human embryonic anatomy has been the resolution of the tools available. The term ‘sonoembryology’ was first coined in, 1990 after the introduction of high-frequency transvaginal transducers. Three-dimensional (3D) sonography performed with a transvaginal approach has expanded the depth of inquiry and allowed three-dimensional sonoembryology. Owing to recent advances of 3D ultrasound technology, ultrasound detection of surface anatomy, organ orientation has rapidly improved its resolution and image quality.

RECENT ADVANCES OF 3D ULTRASONOGRAPHY

Recent advances of 3D/4D sonography have assessed not only structural but also functional early human development.

3D images of embryos were generated using the high-frequency transvaginal transducer (Voluson® E8 with 12 MHz/256 element transvaginal transducer, GE Health care, Milwaukee, USA). Demonstration of an embryo of less than 10 mm (greatest length) has been difficult in the past and not visualized in detail. Figure 1 illustrates a 5.5 mm long-embryo with its yolk sac at six weeks of gestation, with demonstration of the neural tube. During the early embryonic period, the central nervous system anatomy rapidly changes in appearance. 3D sonography using transvaginal sonography with high-resolution probes allows imaging of early structures in the embryonic brain. This can be accomplished through the use of three orthogonal planes, and “tomographic ultrasound imaging”. Serial examinations allow obtaining similar sections of the fetal brain at different stages of development. Therefore, it is possible to document...
the changes in CNS development from early embryonic period. Figure 2 shows dramatical changes of Sylvian fissures between 20 and 31 weeks demonstrating by transvaginal 3D ultrasound. Observation of the brain cortical development should have a great potential to discover migration disorders during pregnancy. Thoraco-abdominal structures can also be imaged in the first trimester. For example, Figure 3 shows tomographic ultrasound imaging.
of fetal chest and abdomen at 13 weeks of gestation. Clear visualization of the lung-liver interface can be of value in the early diagnosis of thoraco-abdominal abnormalities, such as a diaphragmatic hernia. The detailed structure of small parts, for instance the lenses of eyeballs (Fig. 4) can be visualized by 3D orthogonal view. 3D ultrasound technology will contribute to demonstration of in utero pathological changes of congenital diseases arising in utero.

Color Doppler detection and assessment of brain vessels in the early fetus using a transvaginal approach was reported\(^4,5\) in 1993 and 1994. Clear visualization by transvaginal power Doppler of the common carotid arteries, internal and external carotid arteries, middle cerebral arteries at 12 weeks of gestation was reported in 1996.\(^6\) By using 3D power Doppler technology, the vascular anatomy can now be imaged clearly by identification of the common carotid arteries, internal carotid arteries, circle of Willis and middle cerebral arteries. It is important to stress that such images can be obtained at 12 weeks of gestation. Transvaginal high-resolution power Doppler can demonstrate the fine vascular structure of medullary vessels inside the fetal brain (Fig. 5). The powerful technology of 3D ultrasound will promisingly uncover the veil of unknown etiology of congenital diseases in vivo.

**PRENATAL DIAGNOSIS OF ANATOMICAL CONGENITAL ANOMALIES**

The prenatal diagnosis of congenital anomalies with ultrasound is based upon identification of a substantial departure of normal anatomy. This has been possible in the second and third trimester of pregnancy, and this achievement has made the diagnosis of congenital anomalies one of the objectives of modern prenatal care.

**Facial Anomalies**

A facial anomaly can be associated with a central nervous system anomaly (e.g. holoprosencephaly, Figs 6 and 7), be an isolated finding, or part of a syndrome. Detection of the presence or absence of a nasal bone has been found to be of value in the assessment of aneuploidy in the first trimester of pregnancy (risk assessment for trisomy 21)\(^7-11\) Cicero and her colleagues reported that the nasal bone was absent.
in 113 (0.6%) of the 20,165 chromosomally or phenotypically normal fetuses and in 87 (62.1%) of the 140 fetuses with trisomy 21. 3D sonography allows obtaining a midsagittal section of the fetal face by utilizing the three orthogonal planes, and avoids the pitfall of obtaining a parasagittal view, which could lead to false negative results. Tomographic ultrasound imaging also allows demonstration of facial midline structures in detail, by examining close parallel sections. It is important to be aware that the quality of the orthogonal planes is dependent upon the original plane of acquisition. Rembouskos et al have expressed some reservations about the use of 3D for nasal bone assessment. Benoit and Chaoui described the diagnosis of bilateral or unilateral absence or hypoplasia of nasal bones in second trimester screening for Down syndrome by using 3D sonography with maximal mode rendering. Figure 8 shows craniofacial bony reconstructed image and the midsagittal section of fetal face of normal fetus and trisomy 21 fetuses in the first trimester. A short maxillary length has been associated with trisomy 21. Micrognathia (Fig. 9) can be detected as an isolated structural anomaly, as one of the features of a chromosomal abnormality, or a syndrome. Figure 10 demonstrates the slow jaw development during pregnancy in a case of Pierre-Robin sequence, detected by serial 3D ultrasound scans. Assessment of the facial features, chin development and mandibular size by 3D ultrasound in the second and third trimesters has been reported. Facial abnormalities are often associated with craniosynostosis (Fig. 11) due to deformed cranial structure. Cleft lip and palate is one of common congenital facial anomalies. Cleft lip occurs unilaterally (Fig. 12) or bilaterally (Fig. 13). Recent 3D tomographic ultrasound can demonstrate anterior maxillary structure, indicating the

(lower left) 3D reconstructed image of the fetal face.
(lower right) Facial appearance of aborted baby

Evidence of alveolar cleft presence shown on the Figure 12. Congenital cataract can also be visualized by 3D ultrasound as echogenic structure inside the lenses from as early as 14 weeks of gestation (Fig. 14).

BRAIN ANOMALIES

The brain structure should be understood as a three-dimensional structure.17,18 3D sonographic assessment of premature brain in the early pregnancy was reported from 1995.19,20 From 2000, fetal brain assessment in the second and third trimesters by 3D ultrasound was reported.17,18,21-30 Recent advanced 3D ultrasound has enabled to assess detailed brain structure as an understandable organ. 3D ultrasound abilities, such as tomographic ultrasound imaging and three orthogonal view,

Fig. 7: Arrhinia and exophthalmos at 28 weeks.
(upper figures) Facial abnormality with arrhinia and exophthalmos is demonstrated in a case of holoprosencephaly, semilobar type at 28 weeks.
(lower pictures) Postmortem facial appearance of the same baby
greatly contribute to evaluation of fetal brain morphology. Figure 15 shows transvaginal 3D tomographic coronal, sagittal and axial ultrasound views of intracranial structure in a case of ventriculomegaly at 20 weeks of gestation. Thus, accurate assessment of brain pathology can be done by 3D ultrasound. Cortical development of fetal brain can also be visualized by 3D surface imaging, demonstrating gyral and sulcal development and migration disorder which had been difficult to be detected during pregnancy, can be depicted by 3D ultrasound. Figure 16 demonstrates the asymmetrical cortical development due to migration disorder by 2D ultrasound and 3D surface imaging. Thus, 3D ultrasound surface imaging is useful in objective assessment of brain surface. The cranial bone abnormality, seen in a case of encephalocele, can be also visualized by 3D ultrasound maximum mode imaging as shown in Figure 17.
Fig. 11: Facial abnormality associated with Apert syndrome at 31 weeks. (upper left) 2D sagittal image of the fetal face. Note the marked frontal bossing and low nasal bridge. (upper middle and right) 3D reconstructed images of fetal face. Exophthalmos is clearly visualized. This facial appearance occurs due to craniosynostosis of coronal sutures seen in a case of Apert syndrome. (lower pictures) Postnatal facial appearance of the same baby.

Fig. 12: Cleft lip and palate at 22 weeks. (upper left) Surface image of the fetal face. Left sided cleft lip and deformed nasal structure is clearly demonstrated. (lower left) 3D reconstructed image inside the oral cavity. Cleft palate is visualized. (right white and black) Tomographic ultrasound image of the anterior maxillary structure, indicating the evidence of alveolar cleft presence (arrow).
Fig. 13: Bilateral cleft lip at 35 weeks. Bilateral cleft lip is often overlooked because of its symmetrical facial structure. 3D ultrasound shows the clear visualization of the bilateral cleft lip (upper figure). Lower pictures show postnatal facial appearance of the same baby.

Fig. 14: Congenital cataract at 14 weeks. (left) 2D ultrasound image shows abnormally echogenic structure of eye lenses in a case of holoprosencephaly at 14 weeks. (right) 3D reconstructed image of the fetal face. Cleft palate is also demonstrated.

Fig. 15: Hydrocephalus at 20 weeks. Tomographic ultrasound images of coronal (upper left), sagittal (upper right) and axial (lower) views. Clear visualization of intracranial structure is acquired.
Fig. 16: Asymmetrical cortical formation at 29 weeks. Note the marked difference between left and right cortical appearance (left figures). Right figure demonstrated asymmetrical superficial image of the brain. Clear visualization of the brain surface with asymmetrical gyral/sulcal formation is acquired.

Fig. 17: Encephalocele at 19 weeks. (upper left) Tomographic ultrasound image of the encephalocele with small head. (upper right) 3D reconstructed lateral image of the fetus. Microcephaly with encephalocele is clearly demonstrated. (lower left) 2D bidirectional power Doppler image of the head. The cerebral arteries and veins are visualized between inside and outside of the brain. (lower right) The posteroanterior view of the cranial bones. The round shaped bony defect is demonstrated. S; sagittal suture, L; lambdoid suture.
Vertebra and Spinal Cord Abnormalities

Spina bifida is the most common anomaly of the central nervous system. It is often detected during the second and third trimesters. However, the fundamental basis for this anomaly is a failure of the neural tube to close during early embryonic age. Most reports of the diagnosis of spina bifida in utero have occurred after 12 weeks of gestation. Blaas et al. reported an early diagnosis using 2D and 3D ultrasound before 10 weeks of gestation. Figure 18 shows the early diagnosis of spina bifida in a case of OEIS complex (omphalocele, bladder exstrophy, imperforate anus, spina bifida) at 9 weeks of gestation and Figure 19 demonstrates myelomeningocele at 20 weeks. The vertebral bony structure can be depicted by 3D ultrasound for better understanding the level of spina bifida. Vertebral scoliosis is often seen in cases of limb body wall complex (Fig. 20) or cases of hemivertebra as shown in Figures 21 and 22. In hemivertebra cases, asymmetrical rib number can be also demonstrated. Figure 23 demonstrates an abnormally retroflexed fetus seen in a case of Down’s syndrome. Other rare vertebral abnormalities are shown in Figures 24 and 25. Figure 24 shows fused vertebral bodies in a thoracic part seen in a case of trisomy 18 and Figure 25 shows the segmental spinal dysgenesis, characterized by focal agenesis or dysgenesis of the lumbar or thoracolumbar spine, with focal abnormality of the underlying spinal cord and nerve roots.

Chest-abdominal Abnormalities

Congenital diaphragmatic hernia (CDH) occurs in 1 of every 2000-4000 live births and accounts for 8% of all major congenital anomalies. There are three types of CDH; posterolateral or Bochdalek hernia (occurring at approximately 6 weeks’ gestation), the anterior Morgagni hernia, and a hiatus hernia. The left-sided Bochdalek hernia occurs in approximately 90% of cases. Left-sided hernias allow herniation of both small and large bowel as well as intra-abdominal solid organs into the thoracic cavity. Early diagnosis of CDH in the first trimester has been reported. Figure 26 shows the tomographic ultrasound imaging of Bochdalek hernia at 16 weeks. Early diagnosis of this defect is important for the option of fetal treatment. Congenital cystic adenomatoid malformation (CCAM, Fig. 27) is a benign mass of abnormal lung tissue, located usually on one section of the lung. This condition is caused by overgrowth of abnormal lung tissue that may form fluid filled cysts and have no function of normal lung tissue. Early diagnosis of CCAM by 3D ultrasound was reported. Pleural effusion and ascites (Fig. 28) can be easily diagnosed by both 2D/3D ultrasound. In cases of pleural effusion, the lung is floated inside the fluid, whereas, in cases of pericardiac effusion, the lungs are oppressed to posterior potion of the chest (Fig. 29). Umbilical hernia is often associated with chromosomal abnormality or other syndromic diseases. Figure 30 shows a huge umbilical hernia at 12 weeks.

RENAL AND URINARY ABNORMALITIES

Hydronephrosis (Fig. 31) occasionally occurs during pregnancy. The causes are vary, obstruction or stenosis of
Recent Advances in 3D Assessment of Various Fetal Anomalies

Fig. 20: Vertebral scoliosis associated with limb body wall complex at 20 weeks. Severe vertebral scoliosis, abnormal leg position with one leg missing, umbilical hernia with short umbilical cord are clearly demonstrated by 2D/3D ultrasound. Right two figures show the appearance of the aborted fetus.

Fig. 21: Hemivertebra at 19 weeks. (left) 3D maximum mode image of the fetal back. Scoliosis with asymmetrical number of ribs (left:11 ribs, right: 10 ribs) is clearly demonstrated. (right) 3D image of the vertebral body layer reveals Th12 hemivertebra (red circle) and this hemivertebra should be the cause of scoliosis.

Fig. 22: Three levels hemivertebra at 20 weeks. (left) 3D maximum mode image of the fetal back. Severe scoliosis with asymmetrical number of ribs (left:12 ribs, right: 9 ribs) is clearly demonstrated. (right) 3D image of the vertebral body layer reveals three levels hemivertebrae (Th1-Th3, yellow circle).
Fig. 23: Abnormally retroflexed fetus at 14 weeks. 3D surface images (left and middle) demonstrate abnormally retroflexed fetus. Maxim mode (right) shows fetal bony structure. This rarely abnormal-looking fetus died in utero and trisomy 21 was confirmed.

Fig. 24: Fused vertebra with scoliosis at 13 weeks. (left) 2D image of the vertebra. Fused thoracic vertebrae forms stick-like appearance. 3D reconstructed coronal (middle) and sagittal (right) images. Trisomy 18 was confirmed thereafter.
Recent Advances in 3D Assessment of Various Fetal Anomalies

Fig. 25: Segmental spinal dysgenesis at 27 weeks (3D ultrasound and 3D-CT images). (left and middle) 3D US reconstructed images. Note the focal dysgenesis of the thoracolumbar vertebra, with rib abnormality which indicates features of segmental spinal dysgenesis. (right) 3D-CT scan image of the same fetus. Clear visualization of the bony structure is acquired.

Fig. 26: Congenital diaphragmatic hernia at 16 weeks. Tomographic ultrasound image. Typical Bochdalek hernia is seen. Tomographic image clearly shows oppressed and hypoplastic left lung, heart replacement to the right, and the stomach inside thoracic space.
ureters, posterior urethral valves (Fig. 32) or others. Multicystic dysplastic kidney (MCDK) is a form of renal dysplasia characterized by the presence of multiple cysts of varying size in the kidney and the absence of a normal pelvocaliceal system. Fetal MCDK occasionally decreased its size during pregnancy and it is reported that MCDK size tends to decrease during the first 30 postnatal months.37

### Limb Abnormalities

Limb abnormalities can occur as isolated findings or as one component of a syndrome or sequence. However, only 5% of congenital hand anomalies occur as part of a recognized syndrome.38 Figure 34 shows thin limbs with no other abnormalities in a case of triploidy. Figure 35 demonstrates 3D ultrasound images and postmortem pictures in a case of lethal pterygium syndrome. Pterygium is used to describe webbing of the skin across the joint. The term means “wing-like”. Limb pterygia at birth indicates an abnormal developmental process probably occurring in the first trimester and involving reduced mobility of the webbed limb. Prenatal diagnosis in the first trimester was reported.39 Figure 36 shows unilateral forearm and thumb abnormality.
Fig. 30: Huge omphalocele at 12 weeks. (upper left) Sagittal image from 3D orthogonal view. Increased nuchal translucency is seen. (upper right) Three orthogonal view and reconstructed image of the fetal circulation. Because of the ectopic liver, the umbilical vein and ductus venosus run outside the body toward the heart inside the body. The ductus venosus reversed flow was seen in this case. (lower left) 3D reconstructed images. (lower right) Four selected images from tomographic ultrasound images, demonstrating the relation of ectopic organs and inside organ. After confirming normal chromosome and no other associated anomalies were confirmed, parents decide to continue pregnancy. Postnatal surgery was successful and postoperative course has been favorable.

Fig. 31: Mild hydronephrosis at 27 weeks. Three orthogonal view (left) and 3D reconstructed inverted image of the renal pelvis (right)
Fig. 32: Bilateral hydronephrosis due to posterior urethral valve stenosis at 15 weeks. Tomographic ultrasound coronal image of the bilateral kidneys. Bilateral hydronephrosis with huge bladder occurred due to posterior urethral valve stenosis. Vesico-amniotic shunt at 17 weeks was successfully performed in this case and postnatal course was favorable.

Fig. 33: Multicystic dysplastic kidney (MCDK) at 22 weeks. Tomographic ultrasound image of unilateral MCDK. Note the numerous intrarenal cysts in different size are demonstrated.
Fig. 34: Thin limbs in a case of triploidy at 17 weeks. (upper) 3D US reconstructed images. Small for date baby with abnormal proportion, large head and thin limbs and trunk, is demonstrated. (lower) Postmortem 3D-CT scan image of surface anatomy (left) and bony structure (right) of the same baby.

Fig. 35: Lethal pterygium syndrome detected at 14 weeks. (upper) 3D reconstructed images. Middle image demonstrated the bony structure by maximum mode. The fetus did not move with the same appearance for weeks. (lower) Aborted fetus at 20 weeks. The same appearance as prenatal images is seen. The wing-like shoulders and elbows, finger webs are characteristics of this syndrome.
with no other abnormalities in a case of partial chromosomal abnormality. Figure 37 demonstrates two cases of thanatophoric dysplasia at 19-20 weeks.

Limb abnormalities can occur as isolated findings or as one component of a syndrome or sequence. However, only 5% of congenital hand anomalies occur as part of a recognized syndrome. Figure 34 shows thin limbs with no other abnormalities in a case of triploidy. Figure 35 demonstrates 3D ultrasound images and postmortem pictures in a case of lethal pterygium syndrome. Pterygium is used to describe webbing of the skin across the joint. The term means “wing-like”. Limb pterygia at birth indicates an abnormal developmental process probably occurring in the first trimester and involving reduced mobility of the webbed limb. Prenatal diagnosis in the first trimester was reported. Figure 36 shows unilateral forearm and thumb abnormality with no other abnormalities in a case of partial chromosomal abnormality. Figure 37 demonstrates two cases of thanatophoric dysplasia at 19-20 weeks.

Recent high resolution ultrasound can demonstrate finger/toe abnormality in detail. Polydactyly (Figures 38 and 39), syndactyly (Figs 40 and 41) and cleft hand/toe (Figs 42 to 44) are clearly seen by 3D ultrasound during pregnancy. Thumb abnormality, especially adducted thumb is one of the important signs for assessment of fetal brain development. Genetic hydrocephalus or brain abnormalities which is strongly related to L1CAM gene, are associated with adducted thumbs as shown in Figure 45.

**CONCLUSION**

This article reviews and illustrates the power of high-resolution 3D ultrasound in the definition of normal fetal anatomy as well as in the identification of congenital anomalies. The advances of 3D ultrasound in the last decade is remarkable and has contributed to the field of embryology, fetal physiology and pathology. Further researches by 3D...
Fig. 37: Thanatophoric dysplasia at 19 weeks. 3D reconstructed images and postmortem appearance of two cases (upper and lower cases) with short limbs and abnormally curved femurs, are shown.

Fig. 38: Polydactyly at 14 weeks. Bilateral polydactyly is clearly demonstrated in upper figures. This case has cleft palate (lower left), holoprosencephaly (lower middle) and umbilical artery reversed flow.
Fig. 39: Polydactyly/syndactyly at 19 weeks. 3D reconstructed images of the right toe. The first big toe is demonstrated in the left and middle figures. The right Figure clearly shows 6 toe bones.

Fig. 40: Syndactyly (single finding) at 28 weeks. (left) 3D reconstructed images of the left hand. The forth and fifth fingers are almost the same size and abnormally stretched together. (upper right) Postnatal hand appearance. (lower right) Postnatal X-ray image.

Fig. 41: Syndactyly in a case of Apert syndrome at 31 weeks. (upper) 3D reconstructed images of the foot and hand. All of toes and fingers are stucked together. (lower) Postnatal appearance of foot and hand. The same appearance as prenatal imaging is seen.
